One hundred and twenty-nine adults of the North American cotton bollworm, *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctuidae), originating from Arkansas, Mississippi, and Texas were used to evaluate the extent of allelic variation using 20 microsatellite markers designed for the European *H. armigera*, and employing a panel of five microsatellite markers previously developed for the European *H. armigera*. A panel of 28 primer sets was used to genotype the population for nine autosomal, ten X-linked, and nine Z-linked microsatellite markers. A total of 106 alleles was detected from the three mating types (XY, XX, and ZZ), and the number of alleles per locus ranged from 3 to 12. Three monomorphic loci were identified in the North American populations, which produced a maximum number of 15 alleles in two loci. A dendrogram was constructed to determine genetic differentiation among populations using Nei's genetic distance index and visualized with the software TreeView. A subset of six polymorphic loci were found to be highly informative for intraspecific population
